Problem set 2

Due 2pm Tue. Oct. 16, 2018

Objectives

The goal of this lab is to explore Markov Decision Processes (MDPs) to control a simple discretized robot. You will develop and implement a model of the robot behavior and use it to accomplish a prescribed task.

Deliverables

This project will require you to write code. If you do not have one already, create an account on <http://github.com>, and create a project for this class. Make sure the **well commented** code for this lab is committed and pushed, and submit a link to the repository. For some possible resources on git, see below.

You may work individually or in pairs on this assignment. Each person needs to submit their own solutions, but the team can submit common code. Indicate on your solutions who you worked with, and for each person identify 1) the specific contributions made by each, and 2) an aggregate percentage of the total work done.

Upload your solutions to gradescope.

Preliminaries

- 0(a). What is the link to your (fully commented) github repo for this pset?
- 0(b). Who did you collaborate with?
- 0(c). What were the specific contributions of each team member?
- 0(d). What was the aggregate % contributions of each team member?

1 Setup

Consider a simple robot in a 2D grid world of length L and width W . That is, the robot can be located at any lattice point $(x, y) : 0 \leq x < L, 0 \leq y < W; x, y \in \mathbb{N}$. At each point, the robot can face any of the twelve headings identified by the hours on a clock $h \in \{0 \dots 11\}$, where $h = 0$ represents 12 o'clock is pointing up (i.e. positive y) and $h = 3$ is pointing to the right (i.e. positive x).

In each time step, the robot can choose from several actions. Each singular action will consist of a movement followed by a rotation.

- The robot can choose to take no motion at all, staying still and neither moving nor rotating.
- Otherwise the robot can choose to either move “forwards” or “backwards”.
 - This may cause a pre-rotation error, see below.
 - This will cause the robot move one unit in the direction it is facing, rounded to the nearest cardinal direction.

That is, if the robot is pointing towards either 2, 3, or 4 and opts to move “forwards”, the robot will move one unit in the $+x$ direction. Similarly, if the robot is pointing towards either 11, 0, or 1 and opts to move “backwards”, it will move one unit in the $-y$ direction.

- After the movement, the robot can choose to turn left, not turn, or turn right. A left (counter-clockwise) turn will decrease the heading by 1 (mod 12); right (clockwise) will increase the heading by 1 (mod 12). The robot can also keep the heading constant.
- Attempting to move off of the grid will result in no linear movement, but the rotation portion of the action will still happen.

Note that aside from the at edges of the grids, the robot can only rotate if it also moves forwards or backwards; it can move without rotating though.

The robot has an error probability p_e : if the robot choses to move, it will *first* rotate by $+1$ or $-1 \pmod{12}$ with probability p_e each, before it moves. It will not pre-rotate with probability $1 - 2p_e$. Choosing to stay still (take no motion) will not incur an error rotation.

Create code to simulate this system. You may need to create objects to represent states $s \in S$ and/or actions $a \in A$. Note that the state s will later be used as an index to a matrix/array when computing policies and values.

- 1(a). Create (in code) your state space $S = \{s\}$. What is the size of the state space N_S ?
- 1(b). Create (in code) your action space $A = \{a\}$. What is the size of the action space N_A ?
- 1(c). Write a function that returns the probability $p_{sa}(s')$ given inputs p_e, s, a, s' .
- 1(d). Write a function that uses the above to return a next state s' given error probability p_e , initial state s , and action a . Make sure the returned value s' follows the probability distribution specified by p_{sa} .

2 Problem

Consider the grid world shown below, with $L = W = 6$:

The rewards for each state are independent of heading angle (or action taken). The border states $\{x = 0, x = L, y = 0, y = W\}$ (red, marked X) have reward -100. The lane markers (yellow, marked —) have reward -1. The goal square (green, marked ★) has reward +1. Every other state has reward 0.

- 2(a). Write a function that returns the reward $R(s)$ given input s .

3 Policy iteration

Assume an initial policy π_0 of taking the action that gets you closest to the goal square. That is, if the goal is in front of you, move forward; if it is behind you, move backwards; then turn the amount that aligns your next direction of travel closer towards the goal (if necessary). If the goal is directly to your left or right, move forward then turn appropriately.

- 3(a). Create and populate a matrix/array that stores the action $a = \pi_0(s)$ prescribed by the initial policy π_0 when indexed by state s .
- 3(b). Write a function to generate and plot a trajectory of a robot given policy matrix/array π , initial state s_0 , and error probability p_e .
- 3(c). Generate and plot a trajectory of a robot using policy π_0 starting in state $x = 1, y = 4, h = 6$ (i.e. top left corner, pointing down). Assume $p_e = 0$.

- 3(d). Write a function to compute the policy evaluation of a policy π . That is, this function should return a matrix/array of values $v = V^\pi(s)$ when indexed by state s . The inputs will be a matrix/array storing π as above, along with discount factor λ .
- 3(e). What is the value of the trajectory in 3(c)? Use $\lambda = 0.9$.
- 3(f). Write a function that returns a matrix/array π giving the optimal policy given a one-step lookahead on value V .
- 3(g). Combine your functions above in a new function that computes policy iteration on the system, returning optimal policy π^* with optimal value V^* .
- 3(h). Run this function to recompute and plot the trajectory and value of the robot described in 3(c) under the optimal policy π^* .
- 3(i). How much compute time did it take to generate your results from 3(h)? You may want to use your programming language's built-in runtime analysis tool.

4 Value iteration

- 4(a). Using an initial condition $V(s) = 0 \forall s \in S$, write a function (and any necessary subfunctions) to compute value iteration, again returning optimal policy π^* with optimal value V^* .
- 4(b). Run this function to recompute and plot the trajectory and value of the robot described in 3(c) under the optimal policy π^* . Compare these results with those you got from policy iteration in 3(h).
- 4(c). How much compute time did it take to generate your results from 4(b)? Use the same timing method as in 3(i).

5 Additional scenarios

- 5(a). Recompute the robot trajectory and value given initial conditions from 3(c) but with $p_e = 25\%$.
- 5(b). Assume the reward of +1 only applies when the robot is pointing down, e.g. $h \in \{5, 6, 7\}$ in the goal square; the reward is 0 otherwise. Recompute trajectories and values given initial conditions from 3(c) with $p_e \in \{0, 25\%\}$.
- 5(c). Qualitatively describe some conclusions from these scenarios.

Problem Set 2

Due 2pm Thursday Oct. 18, 2018

Preliminaries

0(a) `https://github.com/Sahbaap/ComputationalRoboticsUCLAEE209`

0(b) I did all by myself.

0(c) 100% myself.

0(d) 100% myself.

1 Setup

1(a) The state of the robot is composed of a tuple (x, y, h) where $0 \leq x < L$, $0 \leq y < W$, and $0 \leq h \leq 11$ and $x, y, h \in \mathbb{N}$. So the size of the state space is $N_s = L \times W \times 12$.

Note that I have defined the state class where I can instantiate the state of the robot with any (x, y, h) . Moreover, I have defined the environment class where I can instantiate the maze with given L and W .

State Space

```
1 % just initialization of the state space to have zero values.
2 % as it can be seen, the size of the state space is 12*W*L.
3 % A more useful thing to define is the state class which can be found
4 % in this folder as well.
5 function sp = create_statespace(L,W)
6
7     for k=1:1:12
8         for i=1:1:L
9             for j=1:1:W
10                 sp(i,j,k) = 0.0;
11             end
12         end
13     end
14
15 end
```

State Class

```
1 % this state class generally defines the state of the robot
2 % which includes 'x' and 'y' position of the robot along with its heading 'h'
3 % The state space of this problem is created in the create_statespace
4 classdef state
5     properties
6         x = 0; % 0,1,...,L-1 (L values)
7         y = 0; % 0,1,...,W-1 (W values)

43 end
44
45 end
46 end

```

1(b) The size of the action space is $N_a = 7$. At each time step, the robot can (1) stay and not move, (2) move forward and turn right, (3) move forward and turn left, (4) move forward and not turn, (5) move backward and turn left, (6) move backward and turn right, and (7) move backward and not turn.

Action Class

```

1 % This is the action class which fully defines the robot actions.
2 % 't' represents the translation portion of the robot motion and
3 % 'r' represents the rotation portion of the robot motion. Note that
4 % out of all 9 mixtures, 2 of them (t=0,r=1) and (t=0,r=-1) is not
5 % acceptable. Hence the action space of the robot is composed of
6 % 7 actions:
7 % (1,0)      move forward, no turn
8 % (1,-1)     move forward, turn left
9 % (1,1)      move forward, turn right
10 % (-1,0)     move backward, no turn
11 % (-1,1)     move backward, turn right
12 % (-1,-1)    move backward, turn left
13 % (0,0)      stay still

3(e)

Evaluation of initial policy π_0

The value of the trajectory in 3(c) is -77.36. A plot of V values across the grid with robot's heading (h) be equal to 6, i.e. robot is pointing down, is shown in Fig. 2. Of note, it is expected that the final value of V at goal should be $\frac{1}{1-0.9} = 10$ at infinity time limit which it is.

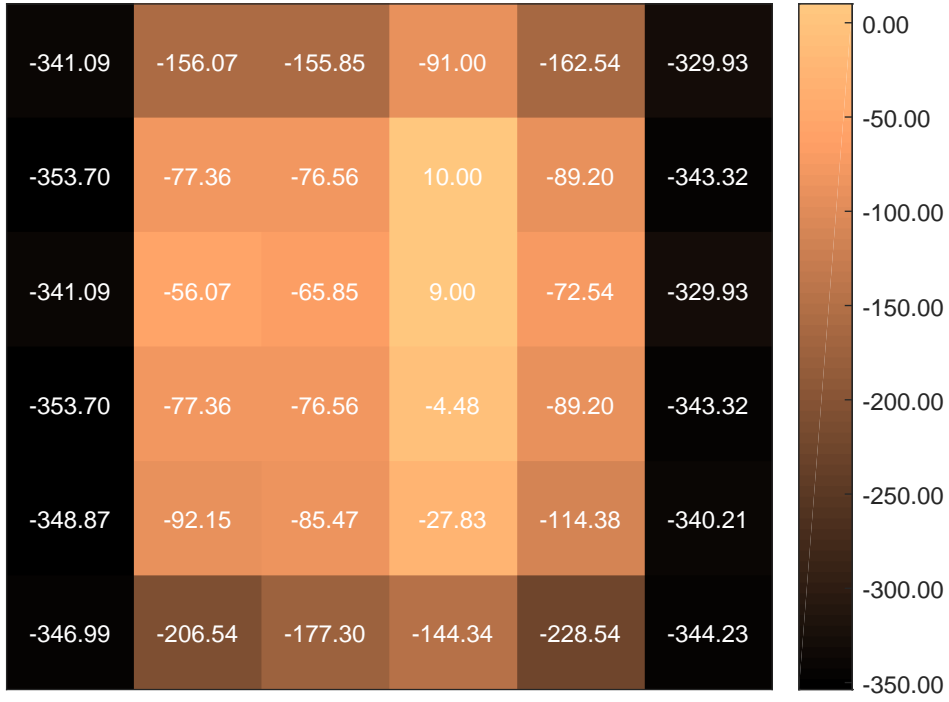

Figure 2: V values of different robot's states (heading = 6) under initial policy.

3(h)

Optimal robot trajectory and value starting at (1,4,6) under P^* and V^*

Under this optimal policy, the V^* of the robot at state (1,4,6) is 3.48. Note that the heat of V is for robot states whose headings are 6. The π^* of the robot is:

- | | | |
|----------------------------|-----------------------------|----------------------------|
| 1- Move Forward, Turn left | 2- Move Forward, No Turn | 3- Move Forward, Turn left |
| 4- Move Forward, No Turn | 5- Move Forward, Turn right | 6- Move Backward, No Turn |
| 7- Move Backward, No Turn | 8- Move Backward, Turn left | |

(a) Optimal Policy (P^*) obtained from policy iteration algorithm.

(b) Optimal Value (V^*) obtained from policy iteration algorithm.

Figure 3: Question 3(h).

3(i) On my Lenovo ThinkPad laptop with 64-bit windows 10, 2.5 GHz CPU and 8 GB RAM, it took 272 (s) for policy iteration to run.

4 Value iteration

4(a)

Value iteration

```
1 % This function takes as argument 'lambda' which is the discount factor
2 % and return the optimal policy 'optimal_policy_VI' and optimal value
3 % 'optimal_value_VI'. This function also return the history of V values
4 % 'V_history_VI' and history of policies 'P_history_VI'.
5 function [optimal_policy_VI,optimal_value_VI] = value_iteration(lambda) %(#AS^2 operations)

98
99 end
100
101 end

```

4(b) The V^* for this policy with initial s_0 at (1,4,6) is 4.30 – see Fig. 4. As it can be seen, both value iteration and policy iteration algorithms yield to identical results for both V^* but with slightly different π^* . This is totally expected as both methods solved the same underlying Bellman equation for V^* . The optimal policy, as it happened here, is not unique however. This means that several optimal policies can result in the same optimal value function. Note that the computational complexity of both methods is also $N_A * N_S^2$. But since they have slightly different approaches, sometimes one converges faster than the other and vice versa. In fact the constant that multiplies to this complexity is different.

The optimal policy in this case is:

- | | | |
|-----------------------------|-----------------------------|-------------------------------|
| 1- Move Forward, Turn left | 2- Move Forward, No Turn | 3- Move Forward, Turn left |
| 4- Move Forward, No Turn | 5- Move Forward, Turn right | 6- Move Backward, Turn right. |
| 7- Move Backward, Turn left | 8- Move Backward, Turn left | |

(a) Optimal Policy (P^*) obtained from value iteration algorithm.

(b) Optimal Policy (P^*) obtained from value iteration algorithm.

Figure 4: Question 4(b).

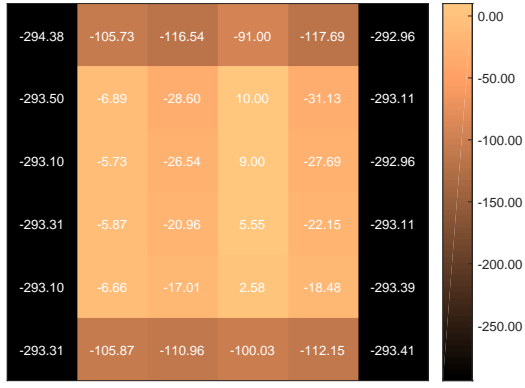

4(c) On my Lenovo ThinkPad laptop with 64-bit windows 10, 2.5 GHz CPU and 8 GB RAM, it took 571 (s) for this value iteration to run. As it can be seen the value iteration took more than two times to converge compared to the policy iteration.

5 Additional scenarios

5(a) With $P_e = 0.25$, The optimal expected V (V^*) for the robot at state (1,4,6) is -6.86. Note that this means that if we run, for example, a Monte Carlo simulation and average the V values under this optimal policy starting at (1,4,6), this averaged V value will be -6.86. However, each time we run the simulation we are going to get V values that are different than -6.86 and their average will eventually converge to -6.86.

In terms of actions also, note that the robot's trajectory changes for every realization of the policy. This means that every time we run our matlab program it gives us different robot trajectory due to the pre-rotation error in our robot which is expressed in P_e .

I have included a plot of expected V values across robot states with heading equal to 6 (see Fig. 5). At the same time I have included different realizations of robot trajectory along with the value of that specific trajectory under the optimal policy.

(a) Expected Optimal Value (V^*) under $P_e = 0.25$

(d) V_3 with value of -8.37

(b) V_1 with value of -14.86

(e) V_4 with value of -3.52

(c) V_2 with value of -10.34

(f) V_5 with value of -4.97

Figure 5: Question 5(a).

5(b) In this section, the robot only gets the final reward with specific headings (5,6,7) rather than all headings. Since the final robot state in previous sections under optimal policy was in the heading 5, when I ran the value iteration or policy iteration algorithms, the same optimal policy and value for the robot at (1,4,6) is obtained (as it can be seen in the Figures.). In this case it took 705 (s) for the value iteration algorithm to converge while it took 422 (s) for the policy iteration to converge. Again value iteration and policy suggests two slightly different trajectories for robot to follow starting at (1,4,6). Fig. 6 and Fig. 7 show these plots.

When $P_e = 0.25$, V^* and P^* change compared to the case where the heading of the robot did not matter at goal point of (3,4). Fig 8 shows the V map at robot heading of 6 and as it can be seen, the V^* of point (1,4,6) which is the expected value of sum of the discounted rewards is -8.30 as opposed to the other case (problem 5a) which was -6.89. In this case it took 798 (s) for the value iteration algorithm to converge and 400 (s) for the policy iteration algorithm.

(a) Optimal Policy (P^*)

(b) Optimal Value (V^*)

(a) Optimal Policy (P^*)

(b) Optimal Value (V^*)

Figure 7: Question 5(b): V^* and P^* for limited heading +1 reward with $P_e = 0$ under policy iteration.

(a) Expected Optimal Value (V^*) under $P_e = 0.25$

(d) V_3 with value of -16.24

(b) V_1 with value of 0.35

(e) V_4 with value of 0.23

(c) V_2 with value of -9.50

(f) V_5 with value of -6.00

Figure 8: Question 5(b).

5(c) The overall time that it took either policy and value iteration algorithms under different heading rewards and p_e is shown in Table 1. It can be seen that the value iteration algorithm overall took longer compared to the policy iteration to converge. Also it can be seen that the limited heading reward took longer to converge than the one where heading does matter for the final reward. Also, it is witnessed that when $P_e = 0.25$ it took longer to converge for the algorithms compared to the $P_e = 0$. This is also expected since the uncertainty makes the robot to explore more on average which in turn makes the algorithm to converge slower.

| | All head. (Pr = 0) | All head. (Pr = 0.25) | limited head. (Pr = 0) | limited head. (Pr = 0.25) |
|------------------|--------------------|-----------------------|------------------------|---------------------------|
| Policy iteration | 272 (s) | 373 (s) | 422 (s) | 477 (s) |
| Value iteration | 571 (s) | 597 (s) | 705 (s) | 798(s) |

Table 1: time to converge for value and policy iteration algorithms.

An interesting point for when P_e was not zero is that for every realization of robot starting at (1,4,6), the trajectory of the robot will be different due to uncertainty from P_e yet the V^* and P^* remain the same, since V^* is in fact averages over all the possible realizations and not individual ones. This is different when P_e is zero since for every realization of the system, the trajectory of the robot and V value for that trajectory remains the same.

When one of the actions that robot can take is to stay still and do nothing, then for some robot trajectories where it needs to pass through those states the robot will stay and cannot hit the goal. Two options at least are available. One is to put some limits on the number of iterations for either value iteration or policy iteration so that if robot did not converge the program will be terminated. In my opinion this is kind of not nice/realistic given the fact that our robot does want to hit the goal and also has other actions to take. The second option is that whenever the optimum policy was to stay still, we do not pick that and find second best action that would maximize the Bellman equation. This is nice since at least staying still would not some how break the program and the robot will hit the goal.

Another interesting point here was that even though both the policy and value iteration algorithms converge to the same V^* , they did not converge to the same optimal policy. This should not be surprising as they solve the same Bellman equation for V^* but it was witnessed that actually different policies can acheive the same V^* values which was an interesting point to learn from this homework.

Another observation is that under some initial conditions and some policies for when $P_e = 0$, the robot would not converge to the goal, for example it could infinitely switch back and forth between two states. This brings up the point that in general this can happen with some specific MDPs. In fact the question is what happens when the agent bounces between two or more states where the actions some states would cancel out the actions in other states and make the agent not able to skip some inner manifolds within the state space. So in this case we would have that the robot would not converge. As a result what I think happens is that in fact having some sort of uncertainty into our dynamics (P_e here) improves the overall convergence behavior of the robot. This is somehow helps the robot to escape the local minimum or some lower dimation optimal manifold within the robot's state space. I believe very similar underlying idea is used for methods like stochastic gradient decent where uncertainty improves escaping unwanted local minimums.
